ABSTRACT

Many analytical or computational applications, especially legacy systems, create documents and display screens in response to user queries “dynamically” or in “real time”. These “virtual documents” do not exist in advance, and thus hypermedia features must be generated “just in time” - automatically and dynamically. Conversely, the hypermedia features may have to cause target documents to be generated or re-generated. This paper addresses some of the challenges faced in developing hypermedia support for virtual documents, including dynamic hypermedia functionality, dynamic regeneration, and dynamic anchor re-identification and re-location. It presents an architecture to support just-in-time hypermedia and discusses issues prompted by this research.

Keywords:
Dynamic hypermedia functionality, Just-in-time hypermedia, Virtual documents, Dynamic regeneration, Re-location, Re-identification, integration architecture

1. INTRODUCTION

Most existing hypermedia systems deal with documents that exist in advance. But for many analytical or computational applications, especially legacy systems, documents or screens are generated dynamically in response to user queries. Such “virtual documents” only exist when the user visits them. When the user closes the window, these documents are gone. For these, hypermedia anchors and destination nodes must be generated “just-in-time”—automatically and dynamically. Furthermore, the hypermedia features leading to virtual documents often cause them to be generated or re-generated.

Virtual documents require an entirely new level of hypermedia support. When traversing links to them, they need to be regenerated. When the user issues a query that creates them anew, the hypermedia system needs to recognize (“re-identify”) them to locate old anchors over the documents or elements within them, even if the contents have shifted. When these elements appear as components within other virtual documents, the hypermedia system needs re-identify the elements and to re-locate anchors for them.

As an example, suppose an analyst wants to determine projected profits for different sales levels in her company. She performs the analysis within a sales support application, and makes comments on each resulting profit calculation. She knows that she will need to include the calculation results and comments. A few days later when preparing her final report, she wishes to return to them without having to remember the input parameter values for each and then manually re-performing each calculation. So she creates a bookmark to the display screen containing each calculation result before closing the window. Invoking each bookmark later causes the sales support application to re-execute its calculations automatically, and the “just-in-time” hypermedia system to re-locate her comments in the application’s newly re-generated display.

Figure 1 illustrates such a parameter screen from our current prototype, which provides just-in-time hypermedia support to an analysis application at NASA. If the user bookmarks the query results, how will the hypermedia system know the parameters to regenerate it? A primary goal is that analytical systems not be altered to integrate hypermedia support, so we cannot simply require developers to reengineer their code to support us by storing and supplying these parameters on demand. Some Web systems regenerate analysis screens by storing all relevant parameters in the virtual document’s URL, and this would solve the problem completely. But many Web-based and non-Web based legacy systems have no such mechanism. Other Web systems do not allow URLs with detailed parameters for security or other reasons. The parameters could be stored in cookies when permitted. But this solution would be local to a single workstation. Furthermore, storing all of the parameters for an active analyst over time would be excessive. This is just one of many problems with hypermedia support of virtual documents.

This research provides a general solution to supplementing virtual documents with just-in-time hypermedia support. We present the requirements and architecture for a Just-in-time Hypermedia Engine, and discuss several of the interesting issues that it surfaces.

1.2 Outline

We begin in §2 by comparing the dynamic hypermedia functionality with static hypermedia functionality. In §3 and §4 we discuss the major challenges encountered in “just-in-time” hypermedia systems: dynamic regeneration, re-location and re-identification. §5 describes related research. In §6 we introduce our prototype architecture and prototype support-
ing “just-in-time” (JIT) hypermedia for virtual documents and analytical applications. §7 concludes with a discussion of our future research and contributions.

2. DYNAMIC VS. STATIC HYPERMEDIA FUNCTIONALITY

Analytical or computation applications currently can take little advantage of hypermedia functionality on the Web. In large part this is due to the predominantly read-only nature of Web applications today, in that most applications do not facilitate functionality that requires the user to add link anchors. But even if this were facilitated (which our JIT hypermedia engine does), most hypermedia functionality only supports static documents for embedding link anchors and target nodes that do not require parameters to generate (unless all parameters are held within the URL - see §3).

Hypermedia functionality includes: structuring functionality (global and local overviews; trails and guided tours; node, link and anchor typing), navigational functionality (structure-based query, history-based navigation and bidirectional linking), and annotation functionality (user-declared links, comments and bookmarks or favorites) [2].

Dynamic hypermedia functionality would apply these over the virtual analytical space of a computational system and the virtual documents generated within it.

The dynamic hypermedia created in this “just-in-time” environment causes problems not found in static environments. A comparison of the dynamic hypermedia functionality with the hypermedia generated in static hypermedia system highlights that:

(a) The destinations of user-declared links, comments and bookmarks, nodes on the history list and overviews, stops along trails and guided tours, are dynamic and virtual. When the user traverses them, the JIT hypermedia system should regenerate the destinations, which normally requires re-executing the commands associated with these destination nodes by using some regeneration rules.

(b) Once a node is regenerated, the JIT hypermedia system must re-locate the anchors that users previously had placed within this node, and should re-identify any elements that the anchors cover as the same ones as before.

(c) When analytical applications generate new query results, the JIT hypermedia system should be able to re-locate and re-identify the anchors for the same elements appearing in other query results. For example, a user adds a comment on an element with global access permissions so that other users see this comment for everywhere that the same element appears. In this situation, every query result containing that same element should have an anchor associated with that global comment.

(d) Overviews and structure-based search (as well as content-based search) over specification links must operate over a hypertext web that does not exist. Instead these functionalities must infer the potential of node and link existence, and node content, based on any available specifications about the nodes and links. Historical record is not enough, for users will not want to see only the nodes that have previously been generated. Instead they want to explore what possibly could be generated by their target application.

The main differences between “just-in-time” hypermedia and static hypermedia is that “just-in-time” hypermedia operates on virtual documents and virtual elements within virtual documents, requires dynamic regeneration, re-location and re-identification. We now discuss these three important issues in more detail.

3. DYNAMIC REGENERATION

Whenever dynamic hypermedia functionality leads users to a virtual document, the JIT hypermedia system must be able to arrange for its regeneration without asking the user to reenter any parameters.

Dynamic regeneration has the following requirements:

(a) A unique and persistent identifier for each virtual document should be generated and recorded. Every time the user traverses a bookmark or other link, he or she should return to the same virtual document, otherwise, these bookmarks or links will no longer be valid. The JIT hypermedia system could keep a list of application commands and parameters that first generated the virtual document in a database keyed to the virtual document identifier. It also could store a document template if available or deductible. When the user first generates the document, the JIT hypermedia system should create a unique ID for this document. When the user tries to revisit it, the application system should use the same ID, retrieve the corresponding commands and parameters from its database, and re-execute the commands to dynamically regenerate the virtual document.

(b) Whenever the JIT hypermedia system receives a document for display, there should be some way for it to reorganize whether the application system has displayed it before. For dynamically-generated documents, the content and document structure could be changed without any notice; there should be some criteria to decide if this is the same document as before. Following are some “sameness” criteria for determining this, listed from very rigid to very flexible:

- The file content and structure should be exactly same (very rigid).
- The file’s structure remains the same, but the content could be different. For example, element values such as...
the current date or current stock price may differ from the last time the document was generated, but these elements will be in the same relative location within the document as before.

- Some critical sections of the document should not change; other sections may.
- As long as the query is the same one that generated it, the system treats it as the same document (very flexible).

Which criterion the application or the user uses depends on his or her requirements. In §1’s example, when the analyst did the query and put some comments on that screen, she felt interested in that particular query on that particular day, so she wants the identical analysis results. If next time when she revisits this comment and the newly-generated document is not same, the JIT hypermedia system should give an “invalid bookmark” or “stale document” warning and allow the user to remove the comment or keep it. On the other hand, sometimes a comment is valid for any content generated by the same query.

(c) A static document that has been edited also has the re-identification problem [11]. Simpler ways exist, however, to indicate that this document has been edited. If a static document is edited, for example, the editing timestamp changes. While in a dynamically-generated virtual document, every time it is generated, the date and time varies. In this situation, even though the file size does not change, the JIT hypermedia system has to re-identify whether this document is the same one as before.

### 3.1 Regeneration Procedure

The regeneration procedure has the following steps:

1. When a user makes a link to a virtual document (a manual link, a bookmark, a link as a step within a guided tour, etc.), the JIT hypermedia system records the virtual document information and the link information. The virtual document information contains a unique identifier for each document, generation command/parameters, etc. If a one-way link is from a virtual document A to a virtual document B, then the link information contains the virtual document identifier A as the source and identifier B as the destination.

2. When the user traverses that link to revisit the virtual document, the JIT hypermedia system retrieves the link information. From the link information, it finds out the destination identifier B, which points to the virtual document B’s information. From this, the hypermedia system gets the necessary command information for its original application to regenerate it (including any parameter information to reexecute the commands).

3. The JIT hypermedia system sends the command information to the underlying analytical application.

4. The underlying application executes the commands and generates a virtual document.

5. The JIT hypermedia system receives the virtual document and revalidates it. Revalidation of a virtual document depends on which sameness criteria the JIT hypermedia system or the user chooses, which we have discussed above.

6. If the regenerated virtual document is revalidated as the same as that generated previously, then the regeneration is successful, otherwise, the JIT hypermedia system gives a “stale document” warning to the user.
Alternatively, when integrating an application with the JIT hypermedia engine (see §6), the integrator could specify "regeneration rules" for each class of virtual documents. The regeneration rule could provide a shortcut set of commands and parameters that can generate the virtual document more directly. If a regeneration rule is available, the JIT hypermedia system could pass all required parameters. For the wizard example, a regeneration rule might bypass the wizard and issue a single command to generate the document directly, using the parameters stored the first time.

Note that we include retrieving static documents (e.g., from a document management application system) as one kind of regeneration. In this case the document is not re-created, but it could have changed since the last time the JIT system displayed it. This still requires revalidation, and re-location and re-identification of the elements within it.

Figures 2 and 3 show screenshots from the JHE prototype. When the user clicks on the blue (i) icon, the system allows him or her to create a bookmark, and as part of this, specify the regeneration criteria. Choosing that bookmark anywhere (from the bookmark list shown in Figure 3) will cause the document in Figure 2 to be regenerated.

3.2 Parameters for Regenerating Virtual Documents

In order to regenerate a virtual document, the JIT hypermedia system should record: dynamic link information, virtual document information, document generation information and document re-validation information. They are described in detail as follows:

**Dynamic Link Information:**

Dynamic links are those leading to a virtual document specification. These include hypermedia services or functionalities such as user-declared links, bookmarks and locations within a guided tour.

*Link identifier:* this should be unique and persistent.

*Title:* link name or label.

*Description:* brief description of this link.

*Virtual document identifier:* which document this link represents.

*User information:* who created this link.

*Date and time:* the date and time this link is created.

**Virtual Document Information**

*Virtual document identifier:* should be unique and persistent.

*Accessibility:* Some groups of users are allowed to activate the commands that create the document; other groups do not have the right. For example, a system administrator should have access to all kinds of information: a manager can view the sales records of his employees, but has no rights to see other groups’ record, a salesperson may have very limited information accessibility. All these access rights are read-only; because these results are from a calculation or query, they should not be changed and there is no way to write these documents back because they are generated dynamically and no longer exist when the window is closed. (An extension to the JIT hypermedia system would be allowing users to save static versions of virtual documents that could be edited, in which case access permissions must be extended to them.)

*) Version:* if the file content or structure changes, mark this as a new version.

*) Title:* the name of this virtual document stored as a display label for its link.

*) Description:* brief description of its specification (e.g., the query or other commands that generate it).

*) Size:* file size.

*) Structure:* element list and the locations of the elements.

*) Metadata:* the metadata of the virtual document and virtual elements within it.

**Revalidation Information**

*Virtual document identifier:* this is the same identifier as in virtual document information above.

*Criterias:* which criteria the JIT hypermedia system or the user chooses to identify the newly-generated virtual document.

*Application identifier:* which application generates this virtual document.

*Command:* which commands are used to generate this virtual document.

*Parameters:* which parameters are used to generate this virtual document.

*Shortcut:* which replacement commands can generate the virtual document more directly.

*Template:* which document template is used to facilitate the generation, if any.

4. RE-LOCATION / RE-IDENTIFICATION

Whenever an application generates or regenerates a document, the JIT hypermedia system needs to determine whether it has encountered that document before (i.e., re-identify it). This is because users may have declared hypertext anchors over the document as a whole, which the hypermedia system should re-locate so users again can access these anchors. In addition, the virtual document’s content could contain elements over which users may have declared hypertext anchors—either within a former appearance of this document or within different documents that contained some of the same elements. For example, a stock’s price could appear in many documents, and a user comment may be relevant to all of its occurrences. Again, the hypermedia system must re-identify these elements so it can re-locate their anchors.

Re-identification and re-locating nodes and anchors have the following complications:

(a) The JIT hypermedia system must recognize the regenerated node is the same one as it opened previously. This issue we have discussed in detail above.
(b) After a virtual document is regenerated, the JIT hypermedia system should be able to find those anchors that were marked in this document previously. This is called re-location.

(c) The JIT hypermedia system must recognize that some content within a newly generated (or regenerated) node is the same element as one marked as an anchor previously. How it decides that an element is the same one depends on some criteria, which will be discussed later in detail.

(d) When the user creates a link, she needs to specify whether it should appear every time the element appears in any node, every time it appears inside that particular node only (e.g., only for that particular query), or only on that particular instance within that particular node [11]. For example, the user may place a comment on a person’s name, but only mean it for one particular paragraph inside a document in which the name is mentioned several times. This is called re-location granularity.

(e) As with a static hypermedia system, the JIT hypermedia system must determine which anchors (and to which links they lead) are available for the re-identified and re-located elements in a (re-)generated node. The unique identifier is crucial here.

4.1 Procedure for Re-location and Re-identification

The re-location and re-identification procedure has the following steps:

1. The first time a user selects and marks an anchor on the screen, the JIT hypermedia system records the anchor information in an external anchor database. Anchor information includes virtual document identifier, location, selection content, granularity, etc. Granularity means different degrees of anchor scopes. An anchor could appear at a particular location in a particular document, on the same element anywhere in a particular document, or could appear in any document that has the same element.

2. After a virtual document is regenerated and re-identified as the same node, the JIT hypermedia system looks for the anchor information for this document in the external anchor database.

3. For each anchor inside this document, the JIT hypermedia system finds the exact position inside the document. The byte offset of an element could change if the document’s content changes between generations. For example, a simple change in the current date could shift byte positions. A flexible and smart internal document-addressing scheme should be used for re-location purposes.

4. For the re-located anchor, the JIT hypermedia system should re-identify that the newly-generated element is the same one that was selected as an anchor. Analogous to virtual document re-identification from §4, the JIT hypermedia system uses “sameness” criteria to decide whether it is the same virtual element. (See §4.2.)

5. After the anchored virtual elements are re-located and re-identified successfully, the JIT hypermedia system, upon demand, can look for those hypermedia functionalities associated with these elements in the database, and associates them with anchors.

4.2 Criteria for Re-location and Re-identification of Virtual Elements

As with virtual document regeneration, once the virtual documents and the virtual elements in the virtual documents are regenerated, there should be some way to recognize which elements are the same ones as before. Following are analogous set of “sameness” criteria for determining this, listed from very rigid to very flexible:

• An element’s value (and perhaps its absolute byte offset) in the document may not change (very rigid).

• The value of the element could be changed, but it should have the same metadata. For example, a person’s age increases every year, but it is still the same element.

• Some metadata may not change, other metadata may.

• The metadata can change as long as it uses the same element name.

Aspects of the element can change as long as it has the same relative position within the structural template associated with the virtual document.

Generally the JIT hypermedia system will require some metadata for the elements to re-identify them. A hypermedia database or central directory should keep this information. When the virtual elements are regenerated, they should be revalidated using the metadata. Also, as with virtual documents, it is up to the application and user requirements to choose the re-identification criteria. The JIT hypermedia system should allow users to change the settings of these criteria or give some warning when the virtual elements are no longer valid. As with virtual documents, virtual elements could be versioned.

5. RELATED WORK

Very little work has been conducted on dynamic regeneration and other aspects of “just-in-time” hypermedia. Related work includes: virtual documents, adaptive hypermedia, and object identification.

5.1 Virtual Documents

A virtual document is a document for which no persistent state exists and for which some or all of each instance is generated at run time. Watters and Shepherd [11] give a number of interesting research issues about these virtual documents, including generation, search, revisiting, versioning, authentication, reference and annotation. Here we expand on some of these.

Reference: How do authors keep track of virtual documents or versions of virtual documents? In our research, we generate and maintain a unique ID for each virtual document, or each version of the virtual document. The JIT hypermedia system maintains information about the virtual documents. When the virtual document is needed, the JIT hypermedia system uses the unique ID to look for the virtual document information, and get the commands and parameters to recreate it if regeneration is necessary.

Generation: When is a virtual document defined? A virtual document can be defined by an author through the use of templates and links, or it can be defined as the result of a search or application. Ranwez and Crampes [3] define virtual documents as a non-organized collection of Information
Bricks (IB), associated with methods allowing the generation of a finished IB sequence. These methods must take into account: predefined links between IBs if any, any parameters supplied, user actions, and a specific generation strategy. In our research, virtual documents normally are created by an application as the result of a user search or query.

**Revisiting:** Users have an expectation that documents found once will be available on a subsequent search. The notion of a bookmark does not apply to virtual documents in its normal, simplistic way. Bookmarks need enough information to recreate the document as it was. The dynamic regeneration in our research has similar purpose.

**Versioning:** Version control has long been a concern of information retrieval research and is now a central issue for managing virtual documents. Users want to be able to return to a bookmarked version of a virtual document, and to navigate forward and backward in time through changes to that virtual document. Some systems such as WikiWeb [19] can recreate Web pages by revisiting the same URL and stores page differences in database, so that it can track the Web page modifications. Also WikiWeb allows users to edit and then store different versions of Web pages, but it supports very little hypermedia functionality.

Some research has been conducted on these issues. Martin and Eklund [4] and Caumanns [5] deal with the creation of dynamic documents by predefined templates or knowledge. Iksal and Garlatti [6] describe an adaptive web application system, which generates adaptive virtual documents by means of a semantic composition engine based on user models. A virtual document is generated by computing components and applying a predefined template. For revisiting purposes, history information is stored and the virtual document is bookmarked. Metadata information about document fragments is stored for versioning purposes. Our research differs from [6] in that, in our research the virtual documents are created by analytical applications; we have no way to control their generation, and the regeneration also depends on the analytical applications. What we particularly are interested in is how to dynamically regenerate the virtual documents, and how to determine that the regenerated one is the same one as before.

Our architecture, however, does not necessarily lead to the regeneration of old versions (unless the application system specifically offers this feature on its own). Just as hypermedia backtracking differs from “undoing” since it takes the user to the current state of a previously visited location, in this research following a bookmark, etc., leads to the current state of the target document.

5.2 Adaptive Hypermedia

Adaptive systems personalize the content of hypermedia and Web pages. They typically focus on the adaptive presentation of content and/or links based on user models that contain information about the user such as knowledge, tasks, attitudes, and interests [7,8]. Iksal and Garlatti [6] generate adaptive virtual documents for author-oriented web applications, providing several reading strategies to readers. An adaptive virtual document can be computed on the fly by means of a semantic composition engine using an overall document structure; an intelligent search engine and semantic metadata relying on semantic web initiative; and the user model. Bailey et al. [8] present a technique for cross-domain adaptive navigational support by combining link augmentation with a model of the user’s spatial context. Cammataro and Pugliese [9] present a graph-based layered model for describing the logical structure of the hypermedia. It also presents an XML-based model for describing metadata about basic information fragments, and “neutral” pages to be adapted. This adaptive hypermedia system is modeled with respect to three different dimensions: user behavior, technology and external environment.

Adaptive hypermedia systems dynamically generate documents based on user models, and the document contents change in successive generations as the user model evolves. However, re-identification and re-location generally is not complex since generation is under the adaptive system’s control instead of being performed by an external analytical system. Nevertheless, techniques about document template design and document structure recognition in these systems could be applied to “just-in-time” hypermedia research.

Furthermore, because adaptive systems do generate their pages, just-in-time hypermedia approaches could be used to provide any hypermedia functionality over that which the native adaptive hypermedia system itself provides.

5.3 Object Identification and Internal Document Structures

An anchor is a selected element (words, a sentence, a paragraph or anything else) in a document, including the entire document itself. After the user creates an anchor, the JIT hypermedia system should remember its selection in the document. The next time its underlying element appears, the JIT hypermedia system should be able to recognize it and associate the proper hypermedia functionality with it. An anchor could have three different degrees of scope: specific, local and generic [11].

**Specific:** only applies to the particular element in the particular document.

**Local:** applies to all the elements with same name in the particular document.

**Generic:** applies to all elements with the same name in all documents.

There are several ways to express the location inside a text file. The HTime [10] standard allows users to express anchors within objects. An anchor may be expressed by:

- Naming - e.g., an SGML entity name or id;
- Counting - e.g., the 234th byte in this file, or the 2nd item in this list;
- Querying - e.g., the first item with a type attribute whose value is 100.

With text files, Microcosm’s main approach for addressing an anchor is using byte offset [11]. Similarly, the Open Hypermedia Protocol (OHP) [20] uses byte offsets (both forward and backward count) to address locations. This can lead to the file editing problem, causing possible link inconsistency. When a static file is edited, links associated with it could become invalid. Microcosm uses date and time stamps to indicate that the file content has been changed, and warns users about the possible link inconsistency. To re-locate the anchors, the forward offset and reverse offset of the anchor are used. Some context (usually 10 characters surrounding
the anchor) is stored. When the anchor can not be found in the previous location, Microcosm searches the file for all occurrences of the context. If only one occurrence is found, Microcosm assumes it is the same anchor and the link is relocated to this new location. This works well but can not guarantee 100% correctness.

Our JHE prototype uses XPath and XPointer for internal document addressing. XPath [21] is a language to address locations inside XML documents based on document structures. XPath models an XML document as a tree of nodes. XPointer [22] is the language to be used as the basis for a fragment identifier for any URI reference that locates an XML resource. Based on XPath, it supports addressing into internal structures of XML documents. As XPath/ XPointer is based on document structure, location expressions can be flexible and accurate if document content changes frequently as long as document structure does not change.

6. The JIT Hypermedia Engine (JHE)

In this section we present our architecture and prototype for a JIT Hypermedia Engine (JHE), as well as how information flows between applications and JHE. JHE extends our prior work with the Dynamic Hypermedia Engine (DHE).

6.1 The Dynamic Hypermedia Engine

To supplement analytical applications with hypermedia functionality, the Dynamic Hypermedia Engine (DHE) [13] intercepts documents and screens as they are about to be displayed on the user interface browser, adding link anchors dynamically over elements it can recognize. When the user selects one of these supplemental anchors, DHE generates a set of relevant links. Choosing one prompts DHE to send a command (e.g., a query) to the target analytical application, causing it to generate a virtual document containing the calculation results. The target application can be the same one that generated the original display or a different one. DHE can often provide this supplemental hypermedia functionality with minimal or no changes to the analytical applications through the use of application wrappers [13, 14], described below.

6.2 Just-in-time Hypermedia Engine Architecture

While DHE dynamically generates link anchors and links for virtual documents, it currently does not support re-identification, re-location or regeneration. The “Just-in-time Hypermedia Engine” (JHE) extends DHE’s architecture to supplement analytical applications with hypermedia functionality in this “just-in-time” environment. JHE’s architecture is shown in Figure 4. In what follows we describe identifiers, the architectural components and the information flow within JHE.

6.2.1 Identifiers

We use XPATH expressions to address the anchors inside the document, and XPOINTER to express arbitrary selections. The unique identifiers (ID) of virtual documents, virtual elements and anchors are generated and maintained by JHE using the following format:

Virtual document identifier = (application ID, command ID, parameter set)
Virtual element identifier = (document ID, element name)
Anchor identifier = (document ID, location)
Parameter set = (parameter1, parameter 2, … parameter n, version number)

JHE groups together the identifiers within each application and within documents they generate. The actual command and parameter values will be filled in at execution time by JHE, but the command format or skeleton is predefined by the application developers at the time they declare their application wrappers (see below). JHE assigns each un-instantiated (not filled-in) command “skeleton” its own ID. For example, a database application may support SQL queries, but each query follows a well-defined format (that can be instantiated in an infinite number of ways).

Anchor location is generated dynamically when it is placed in the virtual document. It is unique inside the document.

Usually a parameter set is composed of multiple parameters and a version number. When one of the parameter’s metadata changes or when a new parameter appears, depending on user settings this virtual document can be treated as a new document (this corresponds to “sameness” criteria level #3 from §3, and a new version number is added to the parameter set) or treated as the same virtual document (this corresponds to “sameness” criteria level #4).

6.2.2 Component Functionality

JHE’s architecture from Figure 4 uses many of the same component modules as DHE. Underlined components are entirely new to JHE and support re-identification, re-location and dynamic regeneration.

User Interface (UI): Usually runs on the user’s computer to display documents, links and JHE commands (e.g., a Web browser providing a Web interface for the underlying analytical system).

Selection Manager (SM): When the user selects a span of content on the UI in order to create an anchor, the SM gets the selection, and records location information.

Document Translator (DT): translates a page in JHE’s internal XML format to an HTML page for display according to the XSL template file.

User Interface Wrapper (UIW): handles communications between the UI and Gateway, and implements the application commands displayed in UI.

Application: A computer application external to the hypermedia system. In this research we focus on analytical applications that dynamically generate virtual documents as the result of user queries.

Application Wrapper (AW): Manages the communication between the Gateway and the application system. It parses the application’s screens and documents to identify the “elements of interest” that JHE will make into link anchors [14]. It also translates these screens and documents into XML pages for JHE internal processing.

It is not always simple to parse a virtual document and then separate the element’s name and value. Parsing is easier when documents and screens follow a well-defined format or template, or if metadata is embedded in, e.g., XML tags that
6.2.3 Information Flow

Information flows through the architecture as follows (shown in figure 5).

(a) Displaying a Document for the First Time

When the user chooses an application function within its display, the JHE Gateway gets the user commands from the UI, translates the necessary information into an internal JHE message and passes this message to the Gateway. The Gateway forwards it to the AW, which passes the commands to its application for execution. The application performs the request and sends the resulting screen or document to the AW for display.

What kind of document or screen the application generates varies by application. The AW translates this source document into an XML document according to the XML Schema file. The XML Schema file could be generated manually or automatically depending on the application data formats. For example, database files are formatted quite well, the semantic structure of the file is very clear, so it is not difficult to generate the XML schema file. Some software, such as XML Spy [16] can automatically generate XML schema (DTDs as well) and translate them into XML files automatically. But for generic text files and other binary files, it is very difficult to do so. So it is up to the AW to provide the semantic data for each application according to the application structure.

After the source document is translated into an XML document successfully, the Document Manager asks the Virtual Document ID Generator to generate a unique ID for the new XML document and records virtual document information. The document ID is a combination of application ID, application specific commands and parameters (which should be unique in a specific application). The mapping between the document ID and the three kinds of parameters assures a unique, persistent ID for each virtual document. Then the Document Manager sends the XML document, together with the document ID to the Gateway. The Gateway sends all this information back to the UIW. The UIW asks the document translator to translate the XML file into an HTML file in order to be displayed on the browser (or to provide a stylesheet if the browser displays XML).

(b) Creating a Hypermedia Construct

Several difference exist between creating a new hypermedia construct (e.g., an anchor, user-declared link or a bookmark) in JHE over the many other hypermedia and open hypermedia systems. Constructs such as anchors are placed within virtual documents. Anchors, for example, will potentially need to be re-identified and re-located within any virtual document displayed. Any document or screen the construct leads to must be potentially re-generated and its endpoint within that document then re-located. Also, when users declare a construct, they can set re-validation (sameness) criteria.
(c) Revisiting a Document

Suppose that later, after the document has been closed, the user wishes to revisit it, e.g., from a bookmark. The UIW sends the bookmark information back to the Gateway, which asks the Regeneration Engine to recreate the execution result. The Regeneration Engine will do the following work. It retrieves the virtual document ID from the bookmark using this virtual document ID. It gets the regeneration information from the database, including some of the following: application information, commands, parameters, re-identification information, generation document template, virtual document history information, versioning information, etc. Then the RE asks the AW to direct the application to re-execute the commands and RE receives the execution result as a XML document (translated by the AW). Using the re-identification criteria and virtual document history information, RE compares the information of the newly-generated virtual document with the history information to revalidate the new document, incorporating some of the techniques used by Davis [11]. If this document is same as the previous one according to the revalidation criteria, then this regeneration is successful. The virtual document sameness criteria are applied here. After this, the Gateway will retrieve all the related hypermedia information for this document, relocating each anchor in the document, and re-identifying it if it is the same as before. For those anchors that are successfully re-located and re-identified, the Gateway sends the related information to the UIW and forms the displayable HTML page.

6.2.4 Prototype

Currently, our JHE prototype provides just-in-time hypermedia support over two computational applications, AskNSDL [17] and NSSDC [18]. The AskNSDL service is a system where users can post questions, which experts in the question domain will answer. One needs to be registered to ask questions but anyone can browse the database of questions and answers later. The NSSDC (NASA’s National Space Science Data Center) is the permanent archive for most NASA astrophysics data. It is housed at the Goddard Space Flight Center in Maryland. In these two systems, users can enter parameters (such as the date) or select from a list of parameters and choose commands or menus, then submit the request. Documents are generated dynamically and then sent back to end users. Document contents vary according to different input parameters.

7. FUTURE RESEARCH

Having a prototype JIT hypermedia engine will allow us to pursue several different strands of research involving dynamic hypermedia functionality.

We intend to evaluate the effectiveness of dynamic hypermedia support. We shall conduct experiments, in which users perform assigned tasks with and without the capacity of dynamic hypermedia functionality.

We plan to adapt existing hypermedia functionalities for dynamic, just-in-time environments. This will mean extending the feature sets of various hypermedia systems to handle virtual documents. As we noted in §2, features such as structural and content search over virtual document speci-
fications instead of stored content, will be especially challenging.

We intend to extend dynamic hypermedia functionality and just-in-time hypermedia support to virtual documents with non-textual contents.

We plan to explore automatically generating the XML templates for and performing an automatic metadata analysis over virtual documents, in order for wrappers to parse and re-identify elements. This will ease the job of writing a wrapper and registering every kind of document in advance. Related research on document templates and document structure analysis will be very helpful to this effort.

We welcome all researchers to join us in these endeavors!

8. CONTRIBUTIONS

This paper introduces new research issues in “just-in-time” hypermedia including dynamic hypermedia functionality, dynamic regeneration of virtual documents; re-identification of re-generated virtual documents, and re-location and re-identification of virtual elements in virtual documents. We have designed and are refining a “just-in-time” hypermedia engine sitting between the browser and the underlying analytical application to supplement hypermedia functionality for applications. We believe our work will also benefit other research fields such as virtual documents and adaptive hypermedia.

We look forward to the day when users of all legacy and Web applications (with any kind of documents and screens—static or virtual) will have access to the full range of hypermedia functionality. Just-in-time hypermedia provides an essential element for achieving this vision.

ACKNOWLEDGEMENTS

We gratefully appreciate funding support for this research by the United Parcel Service, the New Jersey Institute of Technology, and the National Science Foundation under grants IIS-0135531 and DUE-0226075.
